Molt strategy and aging of Rufous-collared Sparrow 
(Zonotrichia capensis) in Bogotá, Colombia

Estrategia de muda y determinación de edad del copetón
(Zonotrichia capensis) en Bogotá, Colombia

ABSTRACT
Molting is an important process of birds’ natural history and learning about molt and plumage allows a better understanding of various aspects of birds’ life. In temperate zones, knowledge about molt strategy, type of plumage characteristics and their association with age are well documented. In contrast, knowledge about molt in Neotropical birds is not well developed. One species with numerous studies regarding molt in several localities is the widely-distributed Rufous-collared Sparrow (Zonotrichia capensis). These studies covered various localities along the species range, facilitating comparisons among populations, and providing an excellent model for the study of plumage and molt variation. In this study, I described both molt strategy and extent of molt Z. capensis costaricensis, through sampling data for one year at two localities in Bogotá city. I captured and banded Z. capensis individuals and collected information about characteristics such as molt limits, skull ossification and iris coloration, which allow for the identification of molt/plumage type and its relation to age categories of a cycle-based age classification system. I found that Z. capensis has a complex basic strategy, where all prebasic molts, including prejuvenal molt, are complete and the preformative molt is a partial molt. The results are congruent with previous findings for this species in some areas. Nevertheless, the molt varies largely in Z. capensis across its distribution and individuals out of Neotropics have an additional partial-incomplete prealternate molt and it is still unknown why.

Key Words. Iris color, plumage, age classification, Neotropics, W–R–P system.

RESUMEN
La muda es un proceso importante de la historia natural de las aves y aprender sobre este proceso permite entender varios aspectos de su vida. En zonas templadas, el conocimiento sobre las estrategias de muda, las características de cada tipo de plumaje y su relación con la edad del ave, son bien conocidas. Por el contrario, en el neotrópico, este conocimiento no está bien desarrollado. Una especie con bastantes estudios sobre muda en varias localidades es el ampliamente distribuido Copetón (Zonotrichia capensis). Esos estudios cubren localidades de su ámbito geográfico facilitando comparaciones entre poblaciones y proveyendo un excelente modelo para estudiar la variación del plumaje y la muda. En este estudio, determiné el alcance y la estrategia de muda de Z. capensis costaricensis mediante muestreos durante un año en dos localidades de Bogotá. Capturé y anillé individuos de Z. capensis y tomé información de características como los límites de muda, osificación del cráneo y color del iris que me permitieron identificar el tipo de plumaje/muda y relacionarlo con una categoría de edad del sistema de clasificación de edad basado en los ciclos de muda. Encontré que Z. capensis tiene una estrategia de muda básica compleja, donde todas las mudas prebásicas, incluida la prejuvenil, son completas y la muda
INTRODUCTION

Molting, an energy demanding activity, is one of the most important processes in birds’ life cycle (Howell et al. 2003, Echeverry-Galvis and Córdoba-Córdoba 2008). Learning about plumage variation, molting, sexing and aging in birds, permit us to understand their ecology and plumage evolution. Furthermore, with long-term monitoring, they will allow a greater understanding of species demography, contributing to more effective decisions on bird conservation (Gómez et al. 2012).

Molt strategies, especially for passerines, are well documented in temperate zones (see Jenni and Winkler 1994, Pyle 1997, 2008). However, patterns present in temperate zones do not completely coincide with those of Neotropical birds, varying in duration and seasonality (Wolf 1969, Ryder and Wolfe 2009). This could be partly due to differences in resource availability throughout the year between these regions (e.g. Miller 1961, Poulin et al. 1992, Echeverry-Galvis and Hau 2013). The new W-R-P system permits classifying tropical birds into age classes (Wolfe et al. 2010, Johnson et al. 2011) and eases the understanding of plumage and molts in tropical birds and leaves an open door for ornithological research (Hernandez 2012, Johnson and Wolfe 2014). Specifically, in Colombia, research about molt and age criteria is a growing research area (e.g. Botero-Delgadillo et al. 2012, Hernández 2012, Gómez et al. 2012, Moreno-Palacios et al. 2013).

The molt of Z. capensis (Müller, 1776) has been fairly well investigated with multiple studies in Colombia and Neotropics (Miller 1961, Wolf 1969, Davis 1971, King 1972, 1973, Zerda et al. 1986, Pyle et al. 2015). Because of this, comparisons can be made among locations, latitudes and populations. In Colombia, the most detailed research about plumage, molt and breeding of Z. capensis was carried out near Cali, Valle del Cauca (Miller 1961). This study established the molt strategy, a brief description of different plumages such as juvenal, formative, basic, and estimates the duration of molt and reproduction seasons for the species.

There exist various studies about plumage, molt and breeding in Z. capensis. The existing information and its broad distribution in Central and South America make of Z. capensis an excellent model to understand the variation of duration and timing in this process in the tropical region. Z. capensis is a widely distributed species and its molt strategy varies across its distribution, even between populations of the same subspecies. In this study, I documented both, strategy and extent of molt in Z. capensis in Bogotá, describing new external characteristics useful for age determination in Bogotá, as iris color. Also, I compared my results with previous investigations and propose the hypothesis of molt variation across latitudinal gradient.

MATERIALS AND METHODS

The study area is located in the Eastern Cordillera of the Colombian Andes, in the city of Bogotá D.C. (2560 m a.s.l.). I established a total of five sampling points, two in the Bogotá Botanical Garden-José Celestino Mutis (4°40’North, 74°6’West) and three in the campus of the Universidad Nacional
RESULTS

Molt strategy and molt pattern
I banded 102 Rufous-collared Sparrows and recaptured 42 during the sampling year. I found that besides the basic plumages, *Z. capensis* counts with a formative plumage. Also, I did not find traces of alternate plumage, as it will be discussed later. Thus, the molt strategy of *Z. capensis* in Bogotá is a Complex Basic Strategy (CBS; sensu Howell et al. 2003). The prebasic molts present a complete molt pattern, i.e. molting all the feathers in the same molting process, and the formative plumage is the result of a partial molt in which flight feathers, primaries, secondaries, tertials, retrices and primary coverts, are not molted. Nevertheless, some captured individuals with a formative plumage had molted tertial feathers (30 %) or central retrices (17 %).

Ageing, molt and plumage description
In Bogotá, I categorized *Z. capensis* in eight age classes within the WRP system (Wolfe et al. 2010, Johnson et al. 2011). The first category, first-cycle prejuvenal molt (FPJ), occurs in the nest when the bird substitutes the natal down plumage for the juvenal. I did not sample nests and I do not have information about the FPJ. The first-cycle juvenal (FCJ) birds are the easiest to identify. They have a juvenal plumage which highly contrasts with posterior plumages. Juvenal plumage presents cryptic colors, brown streaks on stomach and breast and the absence of the specie’s characteristic rufous collar (Fig. 1a). Moreover, 90 % of FCJ birds showed a skull ossification between 0 and 20 % and a raw amber iris color (Table 1; Fig. 2a).

After FCJ, *Z. capensis* reaches a first-cycle preformative molt (FPF). The molt in FPF

Figure 1. Plumages of Rufous-collared Sparrow (Z. capensis costaricensis) in Bogotá, Colombia. a. Juvenal plumage, b. Formative plumage, and c. Basic plumage. Pictures by Diego Cueva.

Age does not include flight feathers. FPF birds presented molting body feathers, brown juvenal feathers on head and remaining streaks on chest, skull ossification under 40 % with a majority under 20 % (Table 1) and a raw amber/chestnut iris color (Fig. 2b). The acquired formative plumage named the next age class, first-cycle formative (FCF; Fig. 1b). As expected (Miller 1961, 1962), formative plumage is superficially similar to later basic plumages (Fig. 1c). Thus, body feathers became useless to classify individuals into an age class. FCF Rufous-collared Sparrow molted all secondary coverts but not primary coverts, they exhibited molt-limits between greater
coverts and primaries coverts. Juvenile primary coverts had an external buffy (Fig. 3a) color that almost disappears in posterior moltings (Fig. 3b). Also, external retrices (juvenal) were narrower shaped, and flight feathers presented aligned growth bars. The preformative molt extent is similar to the one described for *Z. capensis* in other regions (Pyle et al., 2015) and for other *Zonotrichia* species (Pyle 1997). Furthermore, 77% of captured FCF individuals had ossification between 20 and 60%, and 54% of the total FCF birds did not get over 40% ossification. Finally, 77% FCF individuals presented a chestnut colored iris, and 23% presented an intermediate iris color, between chestnut and definitive Pratt’s Rufous color (Table 1; Fig. 2b).

After FCF, *Z. capensis* turned into a second-cycle prebasic molt (SPB) individual. At this stage, 64% of the individuals still have skull windows, most of them with skull ossification between 80 and 95%. Also, 68% of the birds presented an intermediate iris color between chestnut and Pratt’s Rufous (Fig. 2c). Finally, juvenal primaries, secondaries, retrices and primary coverts can be identified before they are completely molted, according to the descriptions of the FCF birds. After second prebasic molt, *Z. capensis* enters into the second-cycle basic (SCB) age class. Birds in this stage did not show differences with subsequent plumages. Nevertheless, some individuals, presumably at the beginning of the SCB, presented skull windows and iris that did not reach a Pratt’s Rufous coloration yet (Fig. 2c) permitting age identification. However, at this stage, *Z. capensis* develops the final iris color, Pratt’s Rufous, and completes skull ossification, making birds indistinguishable from birds in definitive-cycle basic (DCB). This forces categorization as after first cycle (FAJ), following Wolfe et al. (2010) and Johnson et al. (2011).

Finally, definitive prebasic molt (DPB) birds differ from previous molt stages because the primaries, secondaries and primaries coverts are not juvenal and do not present the characteristics described in the FCF section. Furthermore, the individuals have a Pratt’s Rufous iris (Fig. 2d) and a completely ossified skull. The definitive-cycle basic (DCB) birds have a plumage that will not change in posterior cycles. Moreover, they present a Pratt’s Rufous iris color and 100% skull ossification.

Additionally, I captured several times an individual 7.4 years old, first banded by the Ornithology Group of Universidad Nacional de Colombia (GOUN) on the 20th Sep 2006 and last time captured on the 16th Feb 2014. This bird allowed me to confirm the characteristics of DCB. Also, outstanding captures were two FCF females with high feather wear, category three over four, and developed brood patch. Moreover, seven males with suspended molt (P2-3), all with a cloacal protuberance. These captures highlight that in Bogotá *Z. capensis* reach sexual maturity and can reproduce at an early age class, during the FCF. Finally, the seven males are evidence of molt suspension due to overlapping with reproduction. Similar cases were found in Tucumán, Argentina (King 1972, 1973).

**DISCUSSION**

In Bogotá *Z. capensis* has a Complex Basic Strategy. All prebasic molts, including prejuvenal molt, are complete molts. Only the preformative molt is a partial molt. The strategy and extent of the molts in Bogotá do not differ from the populations around Cali, Colombia (~3° North; Miller 1961). Furthermore, both populations did not show evidence of alternate plumage, differently from several studies occurred at higher
latitudes such as Costa Rica (~10° North, Wolf 1969), Peru (~12° South, Davis 1971) and Chile (~30° South, Pyle et al. 2015), where an alternate plumage was present. However, studied populations of Z. capensis in Tucumán, Argentina (King 1972, 1973) did not show prealternate plumage either.

A second important fact about molt of Z. capensis is that reported by Miller (1961) indicating individuals going through two complete prebasic molts in a single calendar year. Is it possible that the incomplete alternate molt reported in Peru by Davis (1971), which included 2-6 primaries, became a complete molt in tropical latitudes? If it is a complete prealternate molt, there is no way to differentiate it from a complete prebasic molt. Even if two molting peaks occur in Cali and Bogotá during the same year (Miller 1961, Zerda et al. 1986), neither of them may be associated with prebasic

Molt strategy of *Z. capensis* in Bogotá

...due to the existence of complete molts all year around (Miller 1961, Zerda et al. 1986). Differently to temperate areas, where most birds respond to an annual climate cycle (Pyle 1997), in the Neotropics *Z. capensis* is subjected to a two-cycle climate year (Miller 1961, Zerda et al. 1986). Here, energy consuming activities such as reproduction have two seasons per year, and a single individual can be part of both (Miller 1961, 1962). I think, there are reasons to believe that *Z. capensis* has two complete prebasic molts, instead of one prebasic and one prealternate molts. Nevertheless, the discussion remains open.

Finally, I want to underline that females are sexually mature at the FCF age. In temperate zones, for most birds, there is only one favorable season for reproduction, when several resources become available. Thus, hatching individuals wait for a complete year to the next reproduction season. Contrastingly, the Neotropics have two climate cycles per year and some species, as *Z. capensis*, have two reproductive seasons (Miller 1962). This way, hatched birds concur with a reproductive peak that occurs approximately six months later, and if they reach sexual maturity, they will start to reproduce. However, subsequent molts will...

---

**Figure 3.** Color variation in primary coverts of *Z. capensis* in Bogotá. **a.** A FPF individual with buffy color on the external border (arrow) of the retained primary coverts and, **b.** a DCB individual without the buffy border after molting the same group of feathers.
be delayed due to the high energy demand during reproduction and this will lead to a trade-off between good quality plumage and early reproduction.

There is not clarity regarding which environmental factors in the Neotropics trigger the physiological process that leads to seasonal reproduction. However, Wikelski et al. (2000) presented evidence that tropical birds can respond to photoperiod variation and used it to synchronize reproduction.
