THIRD TRIMESTER ULTRASOUND SCAN COMBINED WITH A CLINICAL METHOD FOR ACCURATE BIRTHWEIGHT PREDICTION AT TERM: A COHORT STUDY IN SPAIN

Ecografía del tercer trimestre combinada con un método clínico para mejorar la predicción del peso del recién nacido a término: un estudio de cohortes en España

Enrique Castro-Sánchez RN, PhD[3]

Abstract

Objective: To develop and assess an equation based on maternal clinical parameters and third trimester ultrasound biometry (combined method), and compare it with ultrasound-estimated foetal weight (EFW) calculated using the Hadlock 2 formula.

Material and methods: Cohort study. A total of 1,224 women with singleton pregnancies who had undergone foetal ultrasound scanning (USS) at 34 weeks were recruited. The study was conducted at a reference center in Valencia (Spain) between January and December 2016. A gestation-adjusted projection (GAP) method was applied to estimated foetal-weight-for-gestational-age by foetal gender at delivery (EFWa). A multivariate regression was created to estimate foetal weight at term (EFWmr) using anthropometric, demographic, ultrasonographic and obstetric-neonatal variables. EFWa and EFWmr were calculated and compared with actual birthweight.

Results: The proportion for EFWmr within <10% of actual birthweight was greater than EFWa (82% vs. 65%, p<0.001). The mean relative error in foetal-weight predictions by using EFWmr was reduced from 6.7% to 0.9% (difference 5.7% 95% CI: 5.4 to 6.0) paired t-test p<0.001, significantly improving the accuracy attainable with USS. The EFWmr outperformed the GAP method in predicting birthweight, within 1% relative error. For newborns <2,500 g, the proportion of estimates within <10% of the actual birthweight for the EFWmr was greater than that of the EFWa (20.4 vs. 16.3%, p=0.005). For babies with normal birthweight (2,500-3,999 g), EFWmr was a better predictor of birthweight than EFWa (84.5 vs. 65.7%, p<0.001).

Conclusions: Mathematical modelling to predict birthweight improves third trimester routine ul-

RESUMEN

Objetivos: desarrollar y evaluar un modelo predictivo de acuerdo con los parámetros clínicos maternos y la biometría de la ecografía del tercer trimestre, que pueda mejorar el poder de predicción del peso al nacer en el recién nacido a término, en comparación con la estimación calculada por ecografía del peso fetal (PFE) usando la fórmula de Hadlock II.

Materiales y métodos: revisión de 1224 mujeres con embarazos **únicos** que se habían sometido a una ecografía fetal a las 34 semanas (EF). El estudio se realizó en un centro de referencia en Valencia (España) entre enero y diciembre de 2016. Se aplicó un método de proyección ajustada de gestación (PAG) para estimar el peso al nacer para la edad gestacional y sexo fetal en el parto (PFEa). Se creó una regresión multivariante para estimar el peso fetal al nacer (PFErm) mediante variables antropométricas, demográficas, ecográficas y obstétrico-neonatales. Los modelos PFErm y PFEa fueron calculados para comparar sus diferencias respecto al peso real al nacer.

Resultados: la proporción de PFErm dentro de $< 10\%$ del peso real al nacer fue mayor que la de PFEa (82% *vs.* 65%, p < 0,001). El error relativo medio en las predicciones de peso fetal mediante el uso PFErm pasó de 6, a 0,9% (Diferencia de proporciones: 5,7%; IC 95%: 5,4-6,0); medias pareadas: p < 0,001, siendo significativamente mejor que la precisión que puede ser obtenida con el método ecográfico. El PFErm superó al método PAG y predice el peso al nacer con un error relativo del 1%. Para recién nacidos con < 2500 g la proporción de estimaciones del peso real $< 10\%$ del PFErm fue mayor que la del PFEa (20,4% *vs.* 16,3%; p = 0,005). En los recién nacidos con peso normal al nacer (2500-3999 g), la capacidad predictiva para estimar el peso al nacer realizada mediante PFErm fue mejor que la realizada mediante PFEa (84,5% *vs.* 65,7%; p < 0,001).

Conclusiones: el modelo matemático creado para predecir el peso al nacer mejora la medición rutinaria de la ecografía en el tercer trimestre del embarazo para estimar el peso del recién nacido a término.

Palabras clave: embarazo; peso al nacer; ultrasonografía; análisis multivariante; estadística.

INTRODUCTION

Accurate prediction of foetal weight has been of great interest in obstetrics due to its significant impact on the course and outcome of labour and delivery (1, 2). Incorrect estimation of foetal weight can result in multiple and often dangerous complications for the pregnant mother and the foetus (2). It has been suggested that accurate estimation of foetal weight may contribute to successful management during labour and care of the newborn in the neonatal period, and help avoid complications associated with foetal macrosomia or low-birthweight newborns, thereby decreasing perinatal morbidity and mortality (3, 4). Unfortunately, birth weight is unknown until birth takes place. (5) As foetal weight cannot be measured directly, it must be estimated from foetal and maternal anatomical characteristics (3).

Methods for accurate prediction of birthweight prior to delivery are required to establish strategies designed to reduce adverse pregnancy outcomes (5, 6). The tools currently used to estimate foetal weight include the evaluation of foetal growth assessment, and can be broadly classified as maternal methods, clinical methods, and imaging methods like ultrasonography (7, 8). Ultrasound estimation (USS) is more expensive and complicated than maternal or clinical estimation, but it is currently expected to provide a more accurate prediction of birthweight (6). In practice, the most common equations for calculating estimated foetal weight (EFW) by USS are reported to be the Shepard and

Hadlock formulae (9). The currently used Hadlock formula for foetal weight estimation has an error rate of 20%, which may fluctuate depending on the skills of the examiner, equipment base, conditions of the examination, as well as the stage of pregnancy or labour (10-12). Regardless of the formula used, the accuracy of the sonographic estimate of the EFW is affected by suboptimal imaging and biological variation (13, 14). In addition, the accuracy of the sonographic estimate decreases with increasing birthweight (15), and tends to be over-estimated in pregnancies suspected of being large for gestational age (LGA) and underestimated in pregnancies with preterm premature rupture of membranes (PPROM) and suspected foetal growth restriction (FGR) (16). The sensitivity and specificity of the Hadlock formula in the detection of foetal macrosomia are 62% and 93%, respectively (4, 12, 16, 17). The level of intra/inter-observer variability in foetal measurement, and the impact of errors on growth assessment and discrepancies within study designs, exceed 14% with 95% confidence intervals (18-20).

Two large studies have compared foetal weight prediction (clinical method vs. ultrasonography) and found that USS was more accurate than clinical estimation of birthweight in the lower range (<2,500 g) (21). However, this was not the case in the 2,500–4,000 g ranges, where clinical estimation was more precise (22). Finally, both methods were equally adequate in the higher range of birthweight (>4,000 g) (23). On the other hand, Chauhan *et al*. (4) found that ultrasound estimation of foetal weight was more accurate than clinical estimation in preterm pregnancies, but not so in term of post-term pregnancies. Due to such limitation, researchers have explored other sonographic or clinical parameters or a mix of them, correlating with foetal weight, with a higher predictive value.

We therefore aimed to derive a reliable equation based on maternal clinical parameters and third trimester ultrasound biometry (combined method) and compare it with the ultrasound-estimated foetal weight (EFW) calculated using the Hadlock 2 formula.

MATERIAL AND METHODS

Design and population. We performed a prospective cohort study in women seen at La Ribera University Hospital (LRUH) in Valencia (Spain) for pregnancy follow-up and delivery between January and December 2016. We included women with a first prenatal appointment and USS between 5 and 12 weeks of pregnancy, single-foetus pregnancy with no foetal abnormalities, and birth between 38 and 40 weeks. Data on maternal pre-pregnancy weight, symphysis-fundal height measurement (SFH), and USS examination at third trimester (34 weeks) by a gynaecologist had to be documented in the electronic health record. Pregnancies complicated by polyhydramnios, hypothyroidism, preeclampsia, gestational diabetes and oligohydramnios were excluded from the study. The LRUH is a public 300-bed tertiary-level healthcare centre which provides health services to 250,000 people approximately. It is the sole hospital providing maternity services to pregnant women in the area, with an average of 3,000 births per year.

Sample size and sampling. During the study period, 2,017 women consented to be included in the study. A representative sample size was calculated. The null hypothesis was that there were no statistically significant differences in birthweight accuracy between the clinical and sonographic methods. Assuming an expected difference between both estimates of weight (EFWmr and EFWa) greater than or equal to 200 g to consider statistically significant differences, accepting an alpha risk of 0.05 and beta of 0.2 in a two-sided test, a common standard deviation of 450, and a drop-out rate of 30%, then the necessary sample would be 39 participants within each group. However, all pregnant women who agreed to participate during the study period (one year) were included.

Procedure. The opportunity to participate in the study was offered before the assessment. An

informed consent was requested by the gynecologist in charge. At the time of recruitment in the third trimester, demographic variables such as maternal age and country of origin were gathered from electronic maternity records at discharge. Self-reported tobacco use in the third trimester was also obtained from the electronic medical records at the health centres by community midwives during the prenatal control period. All of these data were collected by the researcher in charge. Measurements obtained and recorded on the prenatal charts at LRUH by the community midwife responsible for the women's routine prenatal visits were also evaluated by the researchers at 34 weeks and the delivery date, in order to reduce biased measurements. Data on obstetrical variables were also collected. SFH was measured in centimetres with nonelastic measurement tape from the upper border of the symphysis pubis to the top of the uterine fundus, or reversed direction (13). Ultrasound examinations at 34 weeks were performed by sonographers with appropriate training on the SONOLINE G60 model (SIEMENS). Ultrasound estimated foetal weight (EFW) was calculated using the Hadlock 2 formula (8,20), using four foetal indices: Biparietal diameter (BPD), femur length (FL) and abdominal circumference (AC), recorded at 34 weeks at LRUH (Log 10 weight = 1,326 - 0.00326 AC x FL + 0.0107 HC + 0.0438AC + 0.158 x FL). Birthweight was recorded in the delivery room by midwives following clamping and umbilical cord separation, using a digital scale (SECA®, Vogel & Halke GmbH & Co. Hamburg, Germany) within a 10 g accuracy. Weight was documented in the electronic medical record together with all other birth-related data.

The gestation-adjusted projection (GAP) method was applied to each pregnancy by calculating the ratio between the EFW, at the time of the remote ultrasound, and the median foetal weight for that gestational age by foetal gender (19, 24). This ratio was then multiplied by the median birthweight for the gestational age by foetal gender at delivery resulting in the GAP-predicted birthweight. The

ultrasound estimations (EFWa) were each compared to the actual birthweight. Finally, methods were compared: Estimated foetal weight by GAP method (EFWa) (USS at third trimester with the Hadlock 2 formula adjusted by gestational age at birth and foetal gender), and estimated foetal weight with the combined clinical and GAP method (EFWmr) (multivariate lineal regression method) were calculated to compare with the actual birthweight.

Variables to be measured: Predictive variables were age, gestational weight gain and parity, foetal gender, gestational age at birth (GA, in complete weeks), smoking in 3rd trimester (as dichotomous variable). Gestational weight gain (GWG) was calculated after applying the difference between weight on the day of delivery and weight on the first consultation documented in the clinical record. Pre-pregnancy BMI was calculated taking into account the initial weight (5-8 weeks of pregnancy) and the maternal height squared (kg/m^2). Result variables: Birthweight, gestation-adjusted projection (GAP).

Statistical analyses. Descriptive statistics data are presented as mean and standard deviation for continuous variables, or median and interquartile range for non-normally distributed and categorical variables provided as range and percentage. Normality of continuous variables was assessed using the Kolmogorov-Smirnov test. In the event that variables did not adjust to normality, a non-parametric test was used. In the bivariate analysis, correlations between the dependent (birthweight) and independent variables collected were studied using the Student t-test to compare mean quantitative variables.

All variables with statistical significance ($p < 0.05$) and clinical value were included in a multivariate analysis to identify the most accurate birthweight prediction equation (EFWmr). To analyse the relationship between birthweight and different covariables (clinic, demographic and obstetrical variables), an adjusted multiple linear regression model was applied using a stepwise method for variables shown to have an effect on birthweight. In the linear regression

model, the partial F was used to compare the different models obtained. The principle of parsimony was established in order to select the simplest model with the smallest number of variables.

The accuracy of the different methods (EFWa/EFWmr) for estimating foetal weight was then evaluated by calculating the Pearson correlation R coefficient between the estimated foetal weights obtained using each equation and actual birthweight. Intraclass Correlation Coefficient (ICC) was used to evaluate the degree of agreement of both methods with the actual neonatal weight. Absolute error was defined as the absolute value of EFWa//EFWmr minus the actual birthweight, and the relative error value as the absolute EFWa//EFWmr error divided by the birthweight multiplied by 100.

Mean error differences between both methods were assessed by the paired t-test for Gaussian continuous data. The mean error represents the sum of the positive (overestimation) and negative (underestimation) deviations from the actual birthweight, approximating zero in a method with very low or no systematic error. A threshold of relative error within ±10% of actual birthweight was chosen as the cut-off value for examination accuracy. The percentages of birthweight predictions within 10% of the actual birthweight were calculated and compared using the McNemar test. Each outcome measure was then assessed for overall foetal weight and for three categories of weight <2,500 g, 2,500-<4,000 g, and ≥4,000 g. The overall correlation coefficients of ultrasound-based, and clinically determined estimates were also compared. All statistical tests were performed using the SPSS Version 23 software package (IBM SPSS Inc., 2008 Chicago, IL, USA; www.spss.com); p values of <0.05 reflect statistical significance.

Ethical considerations: The study was conducted in accordance with the basic principles for all medical research (Declaration of Helsinki), respecting the applicable legal precepts regarding the protection of personal data. The study was approved by the Research Ethics Committee of La Ribera University Hospital (Reference no. #441-14). Considerations such as confidentiality, voluntary participation, and full information on the nature of the study were extended to all participants. The attending gynaecologist recruited the women after the third trimester USS and obtained their informed consent to participate in the study.

RESULTS

Of the initial 2,017 pregnant women delivered at the LRUH during the study period, 458 women (22.7%) did not meet the inclusion criteria: 36 (7.9%) twin pregnancies, 27 (5.9%) <35 weeks, 334 (72.9%) >40 weeks at birth, 22 (4.8%) polyhydramnios, 34 (7.4%) oligohydramnios, and five (1.0%) foetal deformities. Missing data from antenatal maternity records resulted in 335 women (16.6%) subsequently excluded from the final analysis: 108 (32.2%) without documented third trimester US, and 227 (67.8%) without SFH recorded.

Therefore, a total of 1,224 (60.7%) pregnancies were finally included for analysis. The mean age of the participants was 31.0 ± 6.0 years (median 32.50, range 18-42), mean gestational age at delivery was 39.14 ± 1.5 weeks (range 35-40), and 48.6% (595/1224) women were primiparous. The mean actual birthweight of the study population was 3,254 ± 448.4 g. Forty-nine (4.0%) had a birthweight of <2,500 g, 1,118 (91.3%) weighed between 2,500-3,999 g, and 57 (4.7%) weighed >4,000g. The demographic and clinical characteristics of the study population are depicted in Table 1.

The variables that showed statistical significance with birthweight in the bivariate analysis were: country of origin (p=0.007), parity (p<0.001), maternal age (p=0.007), pre-gestational BMI (p<0.001), SFH (p<0.001), smoker status (p=0.0012), gestational weight gain (p=0.005) and EFWa (p<0.001).

A multivariable model was performed. The predictive variables and coefficients in the multivariate analysis are shown in Table 2. The following equation was derived: EFWmr (g) = -560.4 + (SFH x 51.6) − (smoker [0=no, 1=yes) x 74.6) + (GAP x 0.59).

Differences for the weight of the newborn between EFWmr and EFWa are shown in Table 3. Actual birthweight had a strong positive Pearson two-tail correlation with both the combined method (EFWmr) and ultrasound (EFWa) estimated foetal weights (R=0.91, $p<0.001$ vs. R=0.87, $p<0.001$, respectively), as shown in Figure 1. The difference in birthweight prediction between both methods (EFWa and EFWmr) and the actual birthweight was analysed. For the EFWa, the difference with the actual birthweight was 187.4g ± 361.4 (95% CI: 167.1-207.7), whereas for the EFWmr the difference was -0.68g ± 315.6 (95% CI: -18.3-17.1), differences being statistically significant, respectively (paired t-test $p<0.001$; $p<0.001$). The difference in weight estimation between the two methods, based on the difference between the estimated weight and the actual final weight, was 188.1g ± 361 (95% CI: 178.2-197.9; paired t-test $p<0.001$). The mean relative value error for

	(3236.22-3271.93)	(0.41-1.55)		(p<0.001) *

ABW: Actual Birth weight; EFWa: estimated foetal weight by third-trimester ultrasound scan using the Hadlock 2 formula adjusted by gestational age at birth and foetal gender; EFWmr: estimated foetal weight by multivariate linear regression; 95% CI: 95% Confidence interval; ICC: intraclass correlation coefficient with the actual birthweight.
*p-value: obtained by reliability analysis using a two-way mixed model with absolute agreement type.

EFWmr was lower than for EFWa (0.97% ± 10.1 vs. 6.67% ± 12.1), and the differences were statistically significant by paired t-test (5.7% ± 2.0, 95%CI: 5.4-6.0, p<0.001).

The proportion of ultrasound estimated weights (EFWa) within <10% of the actual birthweight was significantly lower than that obtained with the combined method (EFWmr) (65.3% vs. 82.7%) the difference being significant (McNemar test, p<0.001). The ICC was significantly higher in the case of the combined method estimation versus actual weight, when compared to ultrasound estimation versus actual weight (0.803 vs. 0.743, p<0.001).

There were statistically significant differences between weight estimation methods by birthweight categories. For newborns with <2,500g birthweight, the proportion of estimates within <10% of the actual birthweight for the EFWmr was significantly greater than for EFWa (20.4% vs. 16.3%, p=0.005). For babies with normal birthweight (2,500-3,999g), the combined method was significantly greater than the ultrasound method (84.5 vs. 65.7%, p<0.001). And finally, in macrosomic newborns (>4,000g) the proportion of estimates within <10% of the actual birthweight for the combined method were lower than the

ultrasound method (100.0 vs. 98.2%), however the differences were not statistically significantly (p=0.238). Table 4 presents the differences in error for both estimations' methods and for different birthweight categories.

DISCUSSION

In this paper, we report a novel multivariable model based on maternal characteristics capable of predicting neonatal weight in a large population of normal pregnancies. Only a few studies have previously compared the predictive capacity of birthweight by clinical and ultrasonic measurements (3, 22, 23, 25, 26). Our results suggest that the EFWmr model that takes into account SFH, smoking and EFWa can adequately estimate neonatal weight at term (mean relative error and prediction within 10%). Additionally, our study shows a statistically significant difference in explaining birthweight when it is compared with EFW by adjusted USS (EFWa).

When the result was compared with actual birthweight, the EFWmr prediction increased its accuracy to within 5.7% of actual birthweight (± 188g), a result improving the findings reported by Emechebe et al. (9.2%; 299 g), and resembling best reported values for clinical methods described by others authors (3, 27, 28). For the ultrasonographic method alone, our results (around 7%) are also consistent with other studies where the mean relative error of predicted birthweight varied from 6% to 12% of actual birthweight (9, 15). Based on our results, EFWmr yields a prediction within 10% of actual birthweight, around 83% in line with the report by Curti et al., (84%) and outperforming the data by Shittu or Kayem *et al.* (70% and 58%, respectively) (13, 26).

Our study has shown that EFWmr is as accurate as EFWa within the normal birthweight range in accordance with other researches that have shown accuracies (mean relative error) between 7–19% (3, 16). Regarding the category under 2,500 g, however, the accuracy of the clinical method is lower. Only 20% of birthweights below the 2,500 g threshold are estimated properly by the clinical method within 10% of actual birthweight, in line with Scioscia or Dudley et al. (8, 29) who reported a mean relative error ranging between 13–19%. In the high birthweight (≥4,000 g) group, the difference in the means was not statistically significant in predicting macrosomic newborns, in line with other studies (3, 19), suggesting that both ultrasound and the clinical method are equally accurate in predicting foetal macrosomia (22).

Overall, the mean relative error for the clinical method was lower than the ultrasound method (1%). This suggests that the clinical method of foetal weight estimation is generally more accurate than the ultrasound method. Whilst our findings are consistent with those reported elsewhere (23, 24), the small proportion of low birthweight and macrosomic newborns in our sample warrants caution in the interpretation of the results and suggests that further studies with larger samples and centred on these subpopulations would be necessary. Interestingly, the mean absolute error can be misleading because it is the sum of positive and negative deviations from actual birthweight, thus artificially reducing the difference between actual birthweight and estimated birthweight. It is a measure of systematic error in each method rather than a variation from birthweight. On the other hand, the mean relative error reflects the variability noted regardless of its direction and, as such, being a more accurate predictor of differences in relation to actual birthweight. Thus, for practical clinical purposes, the variation between predicted birthweight and actual birthweight is best expressed as mean relative error (3, 22).

This study has several limitations. First, it might be argued that the knowledge of ultrasound measurement by the clinician measuring fundal height or the suboptimal record completion identified in our clinical health records would influence later measurements. However, the correlation coefficients relating USS and SFH measurements to birthweight did not depend on the order in which

these measurements were carried out (data not shown), and only available data were analysed. This suggests that the order of measurement did not significantly impact accuracy in our study. Second, extreme birthweight values (<2,500 and >4,000g) were infrequent due to the exclusion criteria used in the study. At present, absolute error in birthweight prediction using USS (EFW) varies from 6% to 12% (3, 5).

Accuracy can be improved in two different ways: first, by controlling the limitations of the technique and second, by adding maternal variables from the multivariate model to the ultrasound measurement. We recommend that further research determine the accuracy of the clinical approach we present here in situations, which can alter the evaluation of birthweight in women with different obstetrics' risk. This study had a strength, such as a representative and large sample size and we used a standardized method of clinical estimation that had been found previously to correlate well with birthweight.

CONCLUSIONS

The EFWmr model outperformed the gestation-adjusted projection (GAP) method, and predicted birthweight within 1% relative error, suggesting that our mathematical model improves the routine ultrasound measurement in the third trimester of pregnancy to estimate the neonatal weight at term.
